

The exudophore, a distinct exudate-producing structure of *Pleurotus ostreatus*, carries an oxidative and secretory transcriptional signature

Abstract

Filamentous fungal colonies differentiate into regions with distinct physiology, but the molecular basis of that differentiation is rarely resolved in cultivated basidiomycetes. Growing *Pleurotus ostreatus* cv. “Harbor Blue P01” in a mycoponic ceramic-tube system, we identified a discrete exudate-producing structure, here termed the *exudophore*, alongside exuding mycelium, aerial (fuzzy) mycelium and mycelial nodules. Comparative 3'-tag transcriptome profiling, analysed under criteria designed to be robust at low replicate number, shows that the exudophore carries the most reproducible tissue signature of the four: 37 of its top 50 specificity-ranked markers are supported by every biological replicate, and four co-expression modules associate with it after correction for multiple testing and for ribosomal RNA content. The signature is coherently oxidative and secretory, comprising alcohol oxidase, an FAD-dependent monooxygenase, cytochrome P450, aldehyde and formate dehydrogenases, an AA9 lytic polysaccharide monooxygenase, multiple transporters, and cyanate and cyanide hydratases. Alcohol oxidase generates extracellular hydrogen peroxide, the co-substrate required by fungal peroxidases, placing the exudophore within the oxidative enzymology characteristic of white-rot decay. Mycelial nodules, by contrast, express cerato-platanin family proteins and small heat-shock proteins consistent with fruiting-body primordium formation. We interpret these data as defining the exudophore as a transcriptionally distinct structure and propose specific, testable hypotheses about its function.

Keywords: *Pleurotus ostreatus*, exudate, fungal differentiation, alcohol oxidase, lytic polysaccharide monooxygenase, mycoponics

This manuscript cannot be completed without material only the authors hold: the morphological description of the exudophore, how it is distinguished from exuding mycelium, and the sampling protocol. Those points are marked [AUTHORS] and are load-bearing for the central claim, since the transcriptional argument rests on the structure being distinguishable in the first place. All quantitative results are generated from the analysis repository and verified by `scripts/32_audit_numbers.py`. Methodological detail is given in the companion resource paper.

053

054

055 1 Introduction

056

057 Filamentous fungi grow as colonies that are physiologically heterogeneous. Regions of
058 the same mycelium differ in age, in nutrient access, in the enzymes they secrete and
059 in their developmental trajectory, and this heterogeneity is functionally important: it
060 underlies foraging, substrate decay and the transition to fruiting. Yet in cultivated
061 basidiomycetes the molecular basis of regional differentiation is rarely resolved, in
062 part because sampling discrete structures from a colony is difficult in conventional
063 solid-substrate culture.

064 Guttation—the exudation of liquid droplets from mycelium—is a widespread
065 and long-observed fungal phenomenon whose function remains debated. Exudates
066 have been variously proposed to serve osmotic regulation, excretion of metabolic
067 by-products, extracellular enzyme deployment, and secondary-metabolite storage.
068 Distinguishing among these possibilities requires knowing which cells produce the
069 droplets and what those cells are transcribing.

070 [AUTHORS: two paragraphs required here.] The first should describe the exu-
071 dophore morphologically: what it looks like, at what scale, how it is distinguished from
072 exuding mycelium, when it appears during culture, and whether comparable structures
073 have been described previously in *Pleurotus* or other genera. The second should state
074 the hypothesis being tested. Without the first, the central claim of this manuscript—
075 that the exudophore is a distinct structure—rests on transcriptional evidence alone,
076 which is weaker than it needs to be.

077 The mycoponic culture system used here [1] grows mycelium on micro-structured
078 ceramic tubes supplied with liquid nutrient medium through a size-exclusion interface.
079 Because the mycelium develops on an accessible surface rather than through an opaque
080 substrate, discrete structures can be identified and sampled individually. We used this
081 to compare four tissue types by 3'-tag transcriptome profiling.

082

083

084 2 Results

085

086 2.1 Two of four tissues yield reproducible signatures

087

088 Transcriptomes were obtained for four tissues with four biological replicates each.
089 The sequencing yielded a low fraction of usable mRNA (analysed in detail in the
090 companion resource paper), so all conclusions here are drawn under criteria chosen
091 to be robust at low replicate number, and four libraries falling below a pre-specified
092 count threshold were excluded.

Tissue specificity was scored with the τ index. Because τ is computed on tissue means, a single outlying replicate can manufacture an apparent marker, so we additionally required that *every* replicate of a tissue exceed the maximum value observed in any sample of any other tissue. Of the top 50 markers per tissue, this was satisfied by 37 for the exudophore and 22 for the nodule, but by only 1 each for exuding and fuzzy mycelium. Independently, weighted gene co-expression network analysis produced 41 modules, of which six showed a tissue association surviving Benjamini–Hochberg correction across all 168 module $\times$ tissue tests—four associated with the exudophore and two with the nodule, and none with either mycelial tissue (Fig. 2a).

That two methods sensitive to different failure modes converge on the same two tissues is the basis for restricting interpretation to the exudophore and the nodule. The absence of a signature for exuding and fuzzy mycelium reflects the resolving power of these libraries and should not be read as an absence of distinct biology in those tissues.

2.2 The exudophore signature is oxidative and secretory

Among the 37 replicate-supported exudophore markers, 24 have a characterised homologue. They fall into four functional groups.

Oxidative enzymes. Alcohol oxidase 1 (EC 1.1.3.13), an FAD-dependent monooxygenase, cytochrome P450 monooxygenase, aldehyde dehydrogenase (EC 1.2.1.3), formate dehydrogenase (EC 1.17.1.9) and peroxisomal catalase (Fig. 1). Alcohol oxidase is notable: it generates hydrogen peroxide extracellularly, and H_2O_2 is the obligatory co-substrate of the class II peroxidases that mediate white-rot lignin attack. Aldehyde and formate dehydrogenases together constitute a route for oxidising aldehydes to CO_2 , consistent with handling reactive carbonyl products.

Carbohydrate-active enzymes. An AA9 family lytic polysaccharide monooxygenase (EC 1.14.99.54), a copper enzyme that oxidatively cleaves crystalline cellulose and itself requires an external electron donor and oxygen.

Transport. An MFS-type transporter, an uncharacterised transporter and an amino-acid permease, consistent with substantial solute movement across the plasma membrane.

Detoxification. Cyanate hydratase (EC 4.2.1.104) and cyanide hydratase (EC 4.2.1.66). Cyanide hydratase is characteristic of fungi that tolerate cyanogenic substrates; its enrichment in an exudate-producing structure is unexpected and, in our view, the single most interesting hypothesis-generating observation in these data.

All 16 replicate-supported markers with a characterised homologue show the same pattern: elevated in both exudophore replicates and unremarkable in all ten libraries of the other three tissues (Fig. 1).

The four exudophore-associated co-expression modules are consistent with this picture and add a growth dimension: the most strongly associated module ($r = +0.91$) enriches for small-subunit rRNA maturation, a ribosome-biogenesis signature. Because these libraries carry a high and variable ribosomal RNA content, we tested this explicitly and found the module eigengene correlates with per-library rRNA fraction at only -0.15 ; the tissue association is unchanged when computed as a partial correlation controlling for it (Fig. 2b). The exudophore therefore appears to be a metabolically active, high-biosynthesis structure rather than a passive site of leakage.

139 2.3 Nodules express a fruiting-body primordium signature

140 The nodule-associated module ($r = +0.85$, 320 genes) enriches for extracellular space
141 and for oxidoreductases acting on CH-OH groups, and contains 22 predicted secreted
142 proteins and 11 carbohydrate-active enzymes. It also enriches for the term “pro-
143 tein aggregate centre”. The replicate-supported nodule markers are independently
144 dominated by cerato-platanin family proteins and small heat-shock proteins. Cerato-
145 platanins are small secreted cysteine-rich proteins associated with fungal development
146 and with fruiting-body formation; small heat-shock proteins prevent protein aggrega-
147 tion, which the module-level enrichment recovers by a wholly different route. Together
148 these support interpretation of the nodule as an early fruiting-body primordium.
149

150

151 2.4 Pairwise contrasts

152
153 The strongest contrast in the dataset is nodule against exudophore (198 genes at
154 $p_{\text{adj}} < 0.05$, $|\log_2 \text{FC}| > 1$), followed by fuzzy mycelium against exudophore (50)
155 and exudophore against exuding mycelium (36). Fuzzy mycelium against exuding
156 mycelium yields essentially none, reproducibly and across two independent refer-
157 ence genomes, which is consistent with these being two presentations of vegetative
158 mycelium rather than distinct differentiated states.
159

160

161 3 Discussion

162

163 **[AUTHORS: this section needs the morphological context to be written**
164 **properly.]** The transcriptional argument is complete, but its interpretation depends
165 on what the exudophore is structurally. The following points are supported by the
166 data as they stand.

167 **An oxidative, H_2O_2 -generating signature in an exudate-producing struc-**
168 **ture suggests a functional link between guttation and extracellular oxida-**
169 **tive chemistry.** Alcohol oxidase and an AA9 lytic polysaccharide monooxygenase
170 both operate extracellularly and both depend on oxygen; the LPMO additionally
171 requires an electron donor. A liquid droplet is a plausible medium in which such
172 chemistry could be organised, and the co-enrichment of transporters is consistent
173 with active loading rather than passive leakage. This suggests a testable prediction:
174 exudate droplets should contain H_2O_2 and oxidoreductase activity, which is directly
175 measurable.

176 **Cyanide and cyanate hydratase enrichment is unexplained and worth**
177 **pursuing.** Neither the medium nor the substrate is obviously cyanogenic. Possible
178 explanations include a constitutive detoxification capacity, a response to a medium
179 component, or a role for these enzymes in nitrogen metabolism, cyanate being a
180 substrate for carbamoyl phosphate turnover.

181 **The ribosome-biogenesis association argues against a degenerative**
182 **interpretation.** Exudation is sometimes framed as excretion or as an artefact of
183 senescence. A structure whose most strongly associated co-expression module concerns
184 ribosome biogenesis is more consistent with active growth.

3.1 Limitations	185
Two of four tissues could not be characterised at the depth achieved, and the exu-	186
dophore result rests on two libraries after quality filtering. The functional annotation	187
covers 41% of the proteome, and lineage-specific secreted proteins—the class most	188
likely to be relevant to a novel structure—are systematically the least likely to be anno-	189
tated, so the signature described here is probably incomplete in a biased direction.	190
All functional assignments are inferred from homology; none has been tested experi-	191
mentally in this organism. The proposed links between the transcriptional signature	192
and exudate function are hypotheses, not conclusions.	193
	194
4 Methods	195
Culture, sequencing, read processing, annotation and statistical analysis are described	196
in full in the companion resource paper, and all code and intermediate results are	197
available in the accompanying repository. In brief: four tissue types with four biological	198
replicates were profiled by poly(A)-selected 3'-end tag sequencing; reads were aligned	199
to <i>P. ostreatus</i> BOM_ss5 (GCA_056149245.1) with an rRNA-complete, 3'-extended	200
annotation; counts were normalised with DESeq2 [2] after excluding libraries below	201
15,000 assigned non-rRNA counts; co-expression modules were derived with WGCNA	202
[3] and corrected with Benjamini–Hochberg [4]; specificity was scored with the τ index	203
[5] on linear normalised counts.	204

Figures

Fig. 1 The exudophore signature is reproducible across replicates. Row-scaled expression of the replicate-supported exudophore markers carrying a characterised homologue, across all 12 retained libraries. Each marker is elevated in both exudophore replicates and unremarkable elsewhere; this is the criterion by which they were selected, and the figure shows the margin by which it is met. τ , tissue-specificity index.

Fig. 2 Co-expression modules corroborate the marker analysis. **a**, Module-tissue correlation; asterisks mark associations surviving Benjamini-Hochberg correction across all 168 tests. Only exudophore and nodule have surviving modules. **b**, Each surviving association compared with its correlation to per-library ribosomal RNA fraction, and recomputed as a partial correlation controlling for it. All six survive, including the exudophore ribosome-biogenesis module.

Fig. 3 Specificity scores and replicate support by tissue. **a**, Distribution of the τ specificity index across all scored genes. **b**, Of the top 50 markers per tissue, the number supported by every biological replicate. The test becomes more stringent as replicate number rises, so counts are not directly comparable across tissues.

Tables

Table 1 Differential expression across all six pairwise contrasts (12 retained libraries, rRNA-removed track; $p_{\text{adj}} < 0.05$, $|\log_2 \text{FC}| > 1$).

Tissue A	Tissue B	DE genes
Nodule	Fuzzy mycelium	239
Nodule	Exudophore	198
Nodule	Exuding mycelium	74
Fuzzy mycelium	Exudophore	50
Exudophore	Exuding mycelium	36
Fuzzy mycelium	Exuding mycelium	2
